(Received 17 February 2021; accepted 28 April 2021; published 13 May 2021)

In α -RuCl₃, an external magnetic field applied within the honeycomb plane can induce a transition from a magnetically ordered state to a disordered state that is potentially related to the Kitaev quantum spin liquid. In zero field, single crystals with minimal stacking faults display a low-temperature state with in-plane zigzag antiferromagnetic order and a three-layer periodicity in the direction perpendicular to the honeycomb planes. Here, we present angle-dependent magnetization, ac susceptibility, and thermal transport data that demonstrate the presence of an additional intermediate-field ordered state at fields below the transition to the disordered phase. Neutron-diffraction results show that the magnetic structure in this phase is characterized by a six-layer periodicity in the direction perpendicular to the honeycomb planes. Theoretically, the intermediate ordered phase can be accounted for by including spin-anisotropic couplings between the layers in a three-dimensional spin model. Together, this demonstrates the importance of interlayer exchange interactions in α -RuCl₃.

DOI: [10.1103/PhysRevB.103.174417](https://doi.org/10.1103/PhysRevB.103.174417)**I. INTRODUCTION**

Frustrated magnets with strong spin-orbit coupling have attracted great interest, largely because of the possibility that they may provide realizations of quantum spin liquids (QSLs), i.e., highly entangled topological states of matter with fractionalized excitations and emergent gauge fields. The Kitaev model on the honeycomb lattice [1] is a unique and solvable example in which spin-flip excitations fractionalize into itinerant Majorana fermions and Ising gauge-field excitations.

The search for realizations of the Kitaev model has uncovered a number of insulating honeycomb-lattice magnets, in which strong spin-orbit coupling generates $J_{\text{eff}} = 1/2$ local moments subject to bond-dependent Ising interactions [2–5]. These include the stoichiometric crystalline materials $A_2\text{IrO}_3$ ($A = \text{Na, Li}$) and α -RuCl₃; however, antiferromagnetic long-range order is realized at low temperatures in these materials. Among them, α -RuCl₃ has attracted immense attention [6–8] for two reasons: (i) Inelastic neutron-scattering experiments have detected [8–11] clear signatures of excitation continua over a significant range of energies, which have been interpreted in terms of proximate spin-liquid behavior [12]. (ii) Magnetic fields applied in the honeycomb plane suppress magnetic order, leading to a spin-liquid-like state, the precise nature of which is under debate [5,13–23]. In fact, the overall temperature–magnetic-field (T - B) phase diagram of α -RuCl₃ is currently under intense scrutiny. In zero field, single crystals with minimal stacking faults show a transition

near $T_N = 7$ K to a low-temperature ordered phase that has a zigzag antiferromagnetic (AFM) structure in a single honeycomb plane, with a three-layer periodicity perpendicular to the planes [8]. Some recent experimental results show that at low temperatures there is evidence for a field-induced transition to an additional ordered state before the zigzag-ordered phase is suppressed. Preliminary evidence for this was seen in ac susceptibility measurements [10], and the thermodynamic nature of the transition was confirmed by heat capacity [24], the magnetocaloric effect (MCE) [11], and magnetic Grüneisen parameter [22] data.

Questions also remain about the full T - B phase diagram at higher fields. The reported quantized thermal Hall conductivity at fields above the disorder threshold [20,25] suggests the presence of an additional topological phase transition at a second, higher field. This appears consistent with reported MCE and inelastic neutron-scattering measurements [11]. However, recent Raman [26,27], terahertz [28], and electron spin resonance spectroscopy [29], as well as Grüneisen parameter measurements [22], do not show a clear signature of such a transition. On the theoretical front, there is still considerable discussion about the appropriate microscopic Hamiltonian describing the magnetism of α -RuCl₃ [30–41]. Clearly, the correct Hamiltonian must account for all of the experimentally observed phases and transitions.

In this paper, multiple experimental probes are used to investigate the intermediate-field ordered phase [42]. Orientation-dependent magnetization and susceptibility

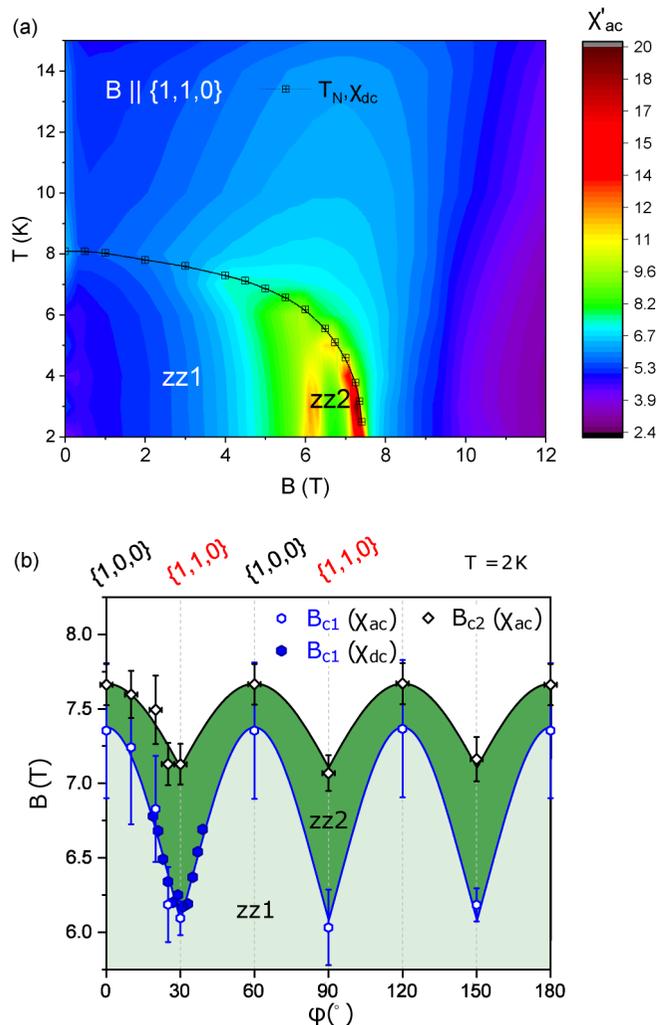

FIG. 1. (a) Temperature–magnetic-field phase diagram of α - RuCl_3 for in-plane fields perpendicular to Ru-Ru bonds (see Fig. 2), as constructed from ac susceptibility measurements. The Néel temperature as extracted from dc susceptibility measurements [10] is shown as black squares for comparison. The dome-shaped intermediate ordered phase $zz2$ occurs between the low-field ordered phase $zz1$ and the disordered phase at higher fields. (b) Phase diagram of α - RuCl_3 at $T = 2$ K as function of in-plane angle and magnetic field from ac and dc susceptibility measurements. The lines are a guide to the eye.

measurements map the phase diagram as a function of magnetic field direction, strength, and temperature; see Fig. 1. Neutron-diffraction measurements show that the intermediate-field ordered state features a periodicity in the direction perpendicular to the honeycomb plane that is different from that of the low-field ordered state, implying that interlayer exchange interactions must be accounted for in order to understand the transition between these two states. To that end, an effective spin Hamiltonian modeling these interactions is introduced, and is shown to describe well the field-induced transition between the two zigzag phases for appropriately chosen model parameters.

The rest of this paper is organized as follows: In Sec. II, we provide experimental details about the measurements

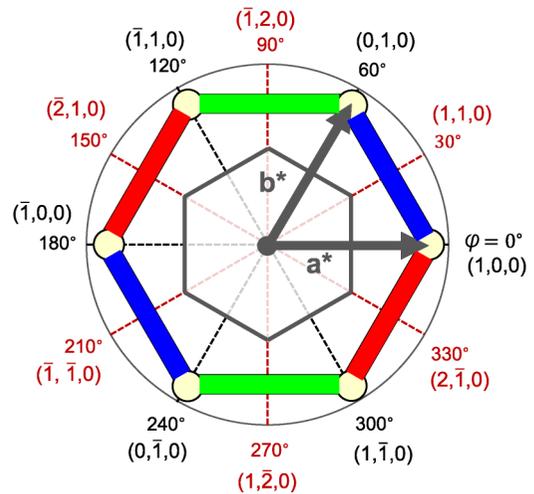

FIG. 2. Definition of the in-plane angle φ within the first Brillouin zone of the two-dimensional (2D) reciprocal lattice (gray hexagon) and with respect to the real-space orientation of the Ru-Ru bonds (red/blue/green). Directions that are equivalent to $(1,0,0)$ (black) and $(1,1,0)$ (red) correspond to angles $\varphi \equiv 0^\circ \text{ mod } 60^\circ$ and $\varphi \equiv 30^\circ \text{ mod } 60^\circ$, respectively. \mathbf{a}^* and \mathbf{b}^* denote the reciprocal-lattice vectors in the $R\bar{3}$ structure.

performed. The presentation of the experimental results starts with the bulk properties in Sec. III, before the neutron diffraction is addressed in Sec. IV. In Sec. V, we present a modeling of the magnetic structure factor. Section VI discusses the properties of a three-dimensional (3D) spin model in an in-plane magnetic field, which is shown to reproduce the key features of the experiment in Sec. VII. Conclusions are presented in Sec. VIII.

II. EXPERIMENTAL METHODS

Susceptibility measurements were performed on α - RuCl_3 single crystals prepared by a vapor transport method described elsewhere [9] and oriented by x-ray Laue diffraction using a conventional $R\bar{3}$ unit cell; see the definition in Fig. 2. Angle-resolved dc magnetization measurements were collected using a sample rotation stage in a 7 T SQUID magnetometer. dc magnetization, ac susceptibility, and thermal-transport measurements were performed up to 14 T at various fixed angles in a Physical Property Measurement System (Quantum Design).

Neutron-diffraction measurements were performed on the CORELLI instrument at the Spallation Neutron Source using an 8 T vertical-field cryomagnet. CORELLI is a time-of-flight instrument with a pseudostatistical chopper, which separates the elastic contribution [44]. For this experiment, a 2 g single crystal of α - RuCl_3 studied earlier [11] was mounted on an aluminum sample holder and aligned with the $(H, 0, L)$ plane in the horizontal scattering plane. In this way, the magnetic field of the 8 T vertical-field cryomagnet is aligned parallel to a $\{1, 1, 0\}$ -equivalent direction. The crystal was rotated through 360° in steps of 4° . Large vertical detector coverage at CORELLI allows access to the full set of magnetic Bragg peaks in the honeycomb two-dimensional (2D) Brillouin zone, which is oriented vertically in this configuration.

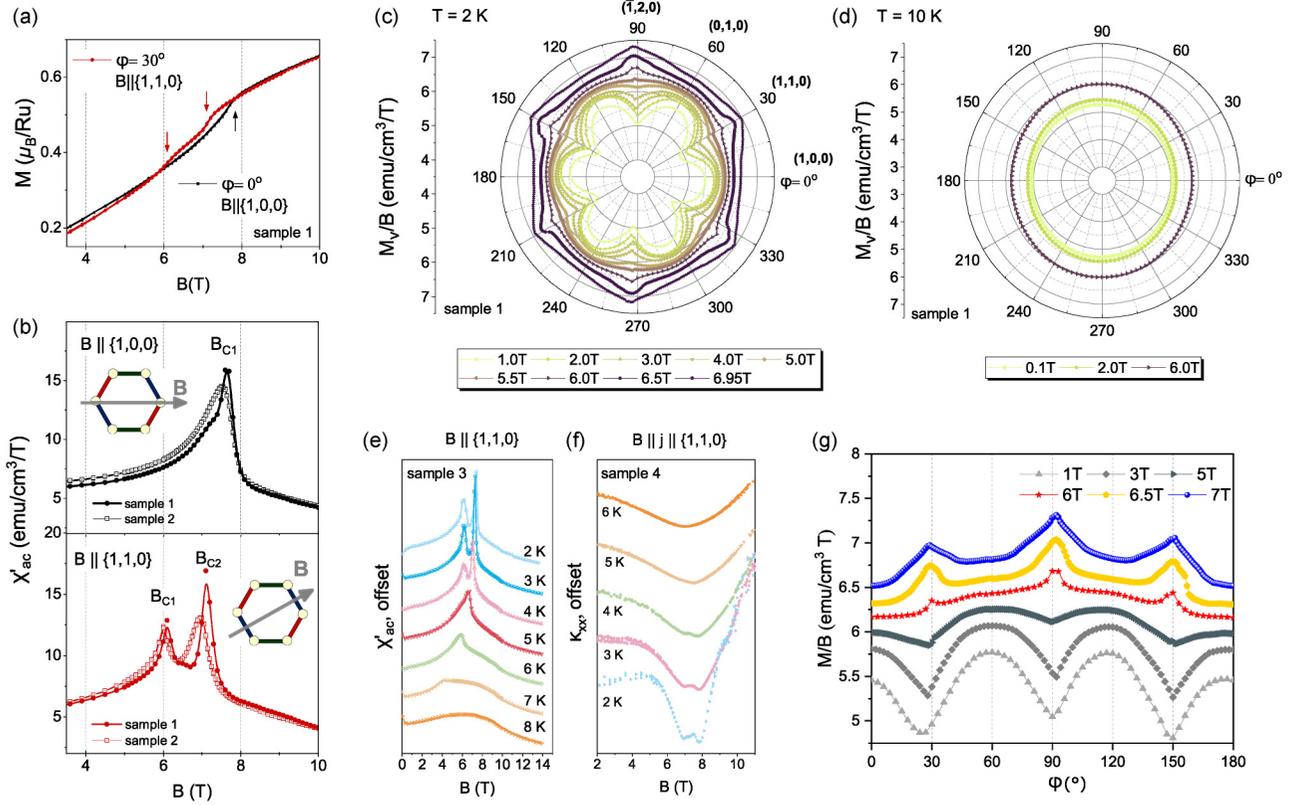

FIG. 3. (a) Field-dependent magnetization for different in-plane field directions φ at $T = 2$ K. Arrows indicate kinks in the magnetization. (b) Real part of the ac susceptibility χ'_{ac} as a function of dc magnetic field for in-plane field directions $\mathbf{B} \parallel \{1, 0, 0\}$ ($\varphi \equiv 0^\circ \pmod{60^\circ}$) (upper panel) and $\mathbf{B} \parallel \{1, 1, 0\}$ ($\varphi \equiv 30^\circ \pmod{60^\circ}$) (lower panel) at $T = 2$ K. The frequency of the 1 mT ac field is 1 kHz. (c) Polar plot of the angular dependence of the dc magnetization (M/B) plotted for various field strengths at $T = 2$ K. A sixfold oscillation as a function of φ is visible. The maxima and minima are reversed around 6 T. (d) The angle dependence of the magnetization above T_N at $T = 10$ K. (e) χ'_{ac} at various fixed temperatures showing two anomalies as a function of $\{1, 1, 0\}$ magnetic field strength for $T \lesssim 4$ K. (f) Thermal conductivity at various fixed temperatures as a function of $\{1, 1, 0\}$ magnetic field strength. The curves in (e) and (f) are offset for clarity. (g) Linear plot of the angle dependence of the magnetization (M/B) at various fields, for $T = 2$ K. The data are the same as those plotted in (c). The exchange of the minima and maxima between 5 and 6 T is clearly visible in this plot.

For all data shown, a measurement at 8 T is subtracted as a background after it was confirmed that no elastic magnetic intensity remained at this field strength. The data were reduced using MANTID [45].

III. BULK PROPERTIES

When a magnetic field \mathbf{B} is applied parallel to a Ru-Ru bond [corresponding to one of the symmetry-equivalent $(1,0,0)$, $(0,1,0)$, or $(-1, 1, 0)$ directions; see Fig. 2], the magnetization at 2 K shows a single kink at $\simeq 7.6$ T in the vicinity of the well-documented field-induced suppression of the zigzag ordered phase [13–19]; see Fig. 3(a). Minor variation between samples is present, as shown in Fig. 3(b). Rotating the magnetic field perpendicular to a bond, i.e., along a $\{1, 1, 0\}$ -equivalent direction, reveals a second feature near 6 T, well below the purported transition into the field-induced disordered phase. The anisotropy of the critical fields within the honeycomb plane is clearly visible in ac susceptibility χ'_{ac} measurements; see Fig. 3(b). Two well-separated anomalies in χ'_{ac} at $B_{c1} \simeq 6$ T and $B_{c2} \simeq 7\text{--}7.3$ T as a function of $\{1, 1, 0\}$ field strength converge and shift slightly higher to $B_{c2} \simeq 7.6$ T in a $\{1, 0, 0\}$ field. This behavior repeats every 60° , consistent

with the symmetry of the honeycomb lattice, and it has been reproduced in a number of samples.

Figures 3(c) and 3(d) show the angle dependence of the magnetization obtained via sample rotation in a field up to 7 T at 2 and 10 K, respectively. Here, φ is the angle between the magnetic field \mathbf{B} and the reciprocal-lattice vector \mathbf{a}^* ; cf. Fig. 2. At moderate fields ≥ 1 T, angle-resolved magnetization below $T_N = 7$ K exhibits a sixfold symmetry with maxima at $\varphi \equiv 0^\circ \pmod{60^\circ}$, where the field coincides with a bond-parallel $\{1, 0, 0\}$ direction. The amplitude of this oscillation decreases with increasing field. At elevated fields ≥ 6 T, a distinct set of maxima appear in a narrow range of φ around the $\{1, 1, 0\}$ directions $\varphi \equiv 30^\circ \pmod{60^\circ}$, also clearly visible in Fig. 3(g). Above T_N , the oscillation in the angle dependence of the magnetization disappears [Fig. 3(d)].

The double-peak behavior in $\chi'_{ac}(B)$ in a $\{1, 1, 0\}$ magnetic field emerges several Kelvin below the Néel transition, becoming distinct only for $T \lesssim 4$ K; see Fig. 3(e). Thermal conductivity measurements exhibit consistent behavior, as shown in Fig. 3(f). A minimum in $\kappa_{xx}(B)$ marking the critical field for the suppression of the zigzag order in α -RuCl₃ has been previously reported [17,19,46]. With $\mathbf{B} \parallel \{1, 1, 0\}$ this feature splits into two distinct minima below 5 K.

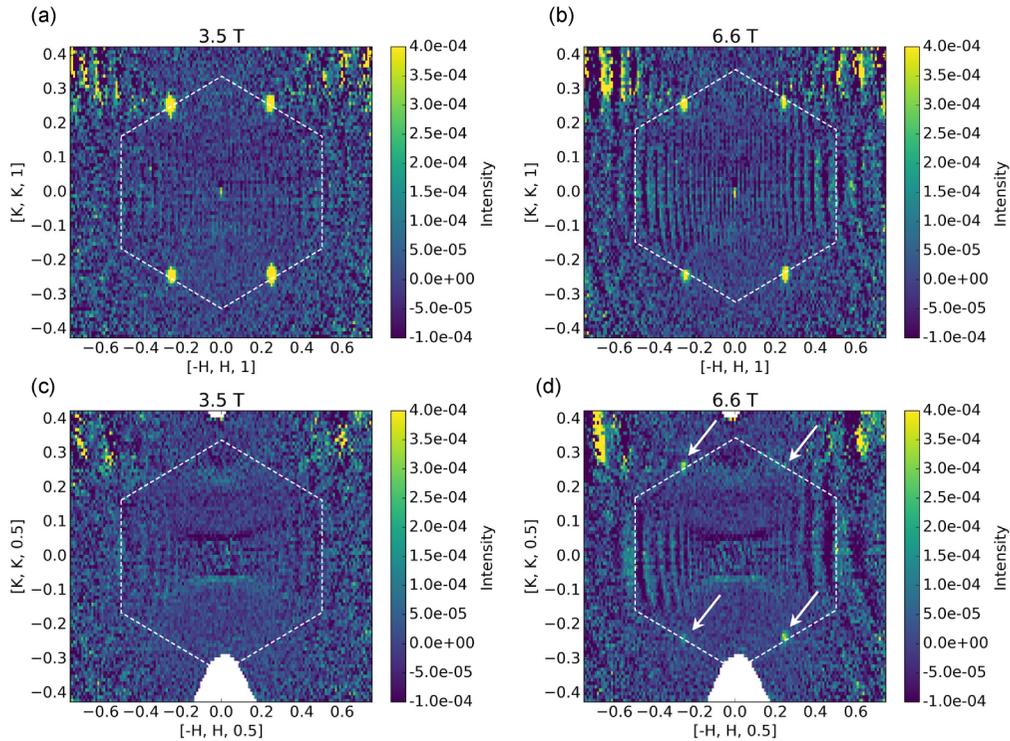

FIG. 4. Top row: Neutron diffraction intensities at $|L| = 1$ for (a) $B = 3.5$ T and (b) $B = 6.6$ T. Magnetic Bragg peaks are visible at the \mathbf{M} points $(1/2, 0, 1)$, $(-1/2, 0, 1)$, $(0, -1/2, 1)$, and $(0, 1/2, 1)$. Bottom row: Intensities at $|L| = 0.5$ for (c) $B = 3.5$ T and (d) $B = 6.6$ T. Additional weak magnetic Bragg peaks appear at the \mathbf{M} points in the 6.6 T data. The perpendicular integration range in is $\Delta L = \pm 0.025$ r.l.u. and the data have been averaged over positive and negative L . The first Brillouin zone is indicated by the dashed hexagon, and the arrows in (d) point to the weak intensity observed at the \mathbf{M} points. The stripy intensity appearing in the upper corners is spurious and caused by imperfect background subtraction for larger wave vectors.

We note that the $\kappa_{xx}(B)$ minima near 7 and 7.8 T are larger than the analogous critical fields in susceptibility data; the detailed field dependence of magnetic contributions to phonon scattering and κ_{xx} enhancement across the two transitions are not well understood and likely play a role in the discrepancy.

IV. NEUTRON DIFFRACTION

To characterize the intermediate-field phase, neutron diffraction data were taken in fields $\mathbf{B} \parallel \{1, 1, 0\}$, for which the two critical fields are separated the most; cf. Fig. 1(b). In Fig. 4, 2D slices of the honeycomb Brillouin zone for field strengths of 3.5 and 6.6 T are shown. The perpendicular wave-vector transfer along L was integrated for narrow ranges around $L = 1$ and 0.5, respectively, and averaged over positive and negative values. At 3.5 T, the intensity of the zigzag magnetic Bragg peaks that remain above the domain repopulation field of 2 T was found to be the strongest [10]. The field of 6.6 T is centered in the intermediate phase between B_{c1} and B_{c2} . Figure 4(a) shows the four $L = 1$ \mathbf{M} -point Bragg peaks at 3.5 T. These four peaks also appear in the intermediate phase at 6.6 T and remain at commensurate positions, as shown in Fig. 4(b) and in one-dimensional (1D) cuts within the honeycomb plane in the Appendix. The most striking feature of the intermediate phase is the appearance of new zigzag Bragg peaks at half-integer values of L , as shown

in Figs. 4(d) and 5(a). No intensity was observed at these L values at lower fields; see Fig. 4(c) for the same slice at 3.5 T.

Since the intermediate phase is also characterized by Bragg peaks of the zigzag structure, we chose the naming convention $zz1$ and $zz2$ for the two ordered phases. Most importantly, the phase transition represents a change of the 3D magnetic structure as indicated by Bragg peaks appearing at different values of L , but at the same positions within the honeycomb plane. The 3D character of the magnetic exchange interactions in α - RuCl_3 has been discussed already in Refs. [11,40] and is confirmed by the observation of this transition.

To explore the nature of the $zz2$ phase in more detail, we show 1D cuts along the out-of-plane wave-vector transfer L in Figs. 5(a) and 5(b). The \mathbf{M} -point intensities in the $zz1$ phase appear at values of $L = \pm 1, \pm 2$, consistent with the three-layer stacking of the crystal structure in the $R\bar{3}$ space group and an obverse-reverse twinning ratio of approximately 50%, as observed in large single-crystals of α - RuCl_3 [47,48]. The Bragg peaks with $L = \pm 2$ appear weaker because of (i) the magnetic form factor and (ii) the neutron polarization factor, which allows only the magnetic moment component perpendicular to the wave-vector transfer \mathbf{Q} to be measured. At 6.6 T, within the $zz2$ phase, the \mathbf{M} -point Bragg peaks with $L = \pm 1, \pm 2$ lose intensity, which can be understood as a consequence of the destabilization of the zigzag order in the vicinity of the transition to the disordered high-field phase. Most importantly, Fig. 5(a) again demonstrates the appearance of the new \mathbf{M} -point Bragg peaks at $L = \pm 0.5$ in the $zz2$ phase.

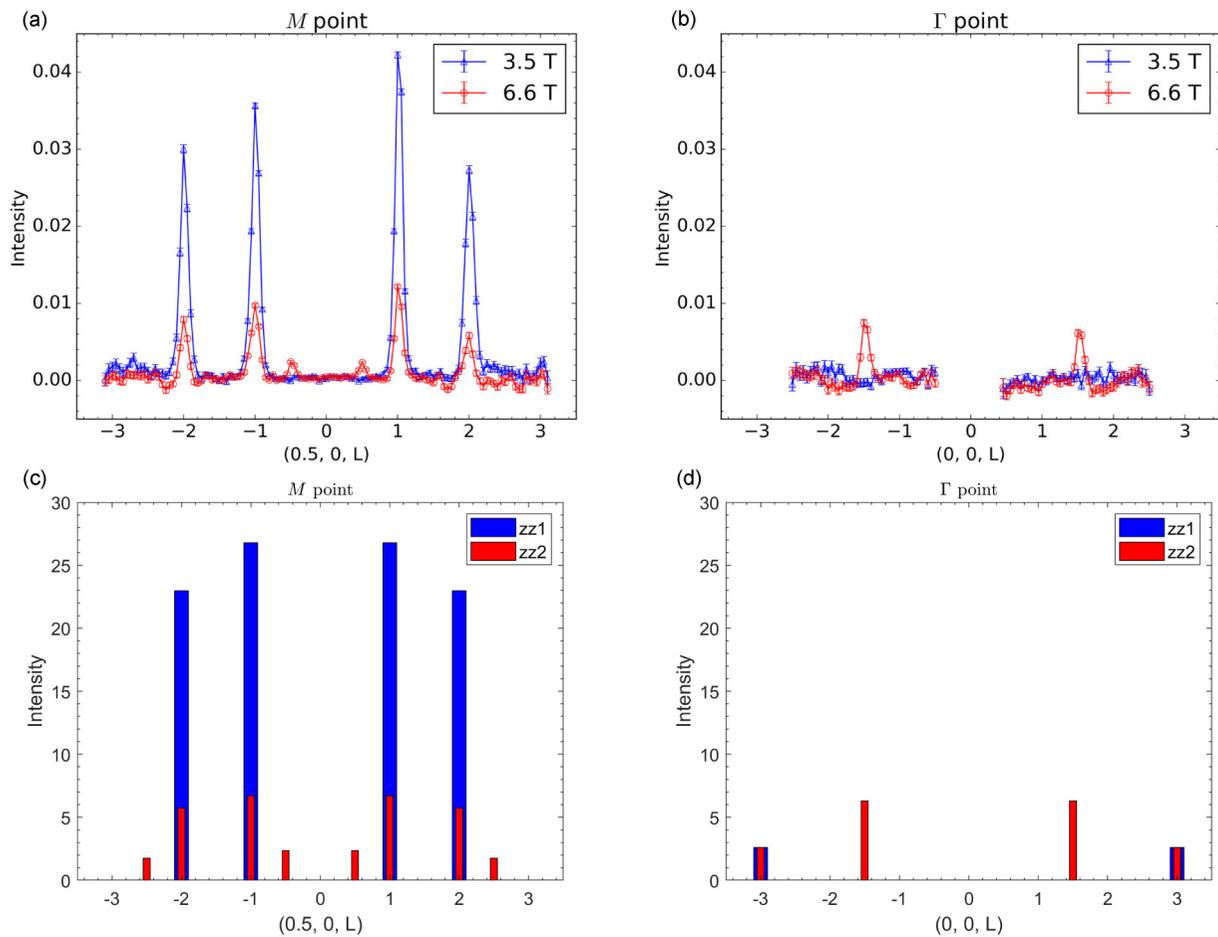

FIG. 5. (a) \mathbf{M} -point $(1/2, 0, L)$ neutron-diffraction intensities as a function of the out-of-plane wave-vector component L for $B = 3.5$ T (blue) and $B = 6.6$ T (red). The intensities have been averaged over the four different \mathbf{M} points shown in Fig. 4. (b) Γ -point neutron-diffraction intensities. The data in (a,b) are integrated in $\Delta H = \pm 0.03$ r.l.u. and $\Delta K = \pm 0.03$ r.l.u.. (c) Magnetic structure factor modeling for the \mathbf{M} point for the $zz1$ (blue) and $zz2$ (red) phases as discussed in the text. Note that the intensities in the $zz2$ phase at integer L are from the $3f$ - zz structure and the ones at half-integer L are from the $6f$ - zz structure; they coexist at intermediate fields. (d) Magnetic structure factor modeling for the Γ point (see the text).

The cut along L for the 2D Γ point $(0, 0, L)$ in Fig. 5(b) reveals another set of magnetic Bragg peaks appearing at $L = \pm 1.5$ in the $zz2$ phase.

The magnetic-field dependence of the different sets of peaks is presented in Fig. 6. At the transition to the $zz2$ phase, the intensity of peaks with integer L exhibits a kink while the half-integer peaks start to emerge. The intensity of the latter goes through a maximum near 6.6 T, and at the transition to the disordered phase, all peaks simultaneously lose their intensities.

V. STRUCTURE FACTOR MODELING

To understand the $zz2$ phase, we performed magnetic structure factor modeling in the $R\bar{3}$ space group for a zigzag magnetic structure on the honeycomb lattice. The $R\bar{3}$ crystal structure is illustrated in Fig. 7. The ordered moments are chosen to lie perpendicular to a Ru-Ru bond in the honeycomb plane, and the angle between the ordered moments and the honeycomb plane was fixed to 15° , as refined from polarized and unpolarized single-crystal neutron-diffraction data [48].

However, with the exception of the relative intensity of the $L = \pm 2$ peaks, the results do not depend on this angle. Two different stackings of the in-plane zigzag configurations along the out-of-plane direction are possible, as illustrated in Fig. 8. The first one is characterized by an antiferromagnetic configuration between nearest interlayer neighbors and is compatible with the threefold stacking of the $R\bar{3}$ crystal structure ($3f$ - zz). All Bragg peak intensities in the $zz1$ phase are correctly reproduced by the $3f$ - zz stacking; see the blue intensities in Fig. 5(c). The second one is characterized by a ferromagnetic alignment between nearest interlayer neighbors. This doubles the magnetic unit cell in the out-of-plane direction and leads to a sixfold zigzag stacking ($6f$ - zz) as shown in Fig. 8(b). This structure consequently leads to magnetic intensities at half-integer positions along L , which in the $R\bar{3}$ space group appear at $L = \pm 0.5, \pm 2.5$. The observation of coexisting integer and half-integer peaks in Fig. 5(a) leads us to assume phase coexistence of the $3f$ - zz and $6f$ - zz structures in the narrow field regime between 6 and 7.3 T, representing the $zz2$ phase. This assumption is supported by our microscopic model below, which characterizes the transition at 6 T as first-order,

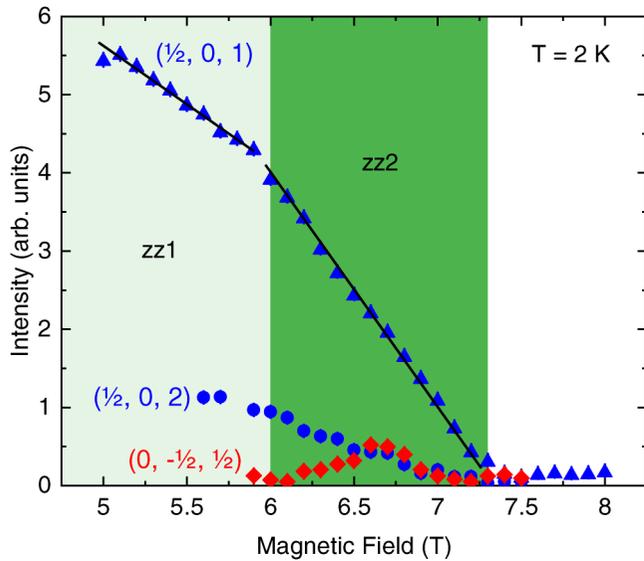

FIG. 6. Intensities of three different magnetic Bragg peaks at 2 K as a function of field strength for $\mathbf{B} \parallel \{1, 1, 0\}$, as obtained from Gaussian fits of 1D cuts through the data at each field strength. The lines are a guide to the eye. Error bars represent one standard deviation of the fitted intensity.

implying hysteresis effects. The volume fractions of the 3f-zz and 6f-zz structures in the zz2 phase can be obtained from the field-dependent peak intensities within the first Brillouin zone. As visible in Fig. 6, the intensity of the $(0, -1/2, 1/2)$ peak goes through a maximum at 6.6 T and at this field value the 6f-zz structure accounts for 1/4 of the ordered moment while 3/4 is still ordered in the 3f-zz structure. It is important to note that the α -RuCl₃ crystal was zero-field-cooled for this experiment, and the field was gradually increased at the base temperature of 2 K.

To model the \mathbf{M} -point intensities in the zz2 phase at 6.6 T [Fig. 5(a)], the magnetic structure factor is calculated for a superposition of the 3f-zz and 6f-zz structures with a ratio of 3/4 to 1/4. For comparison with the experimental data, the overall intensity is reduced by a factor of 4 compared to the zz1

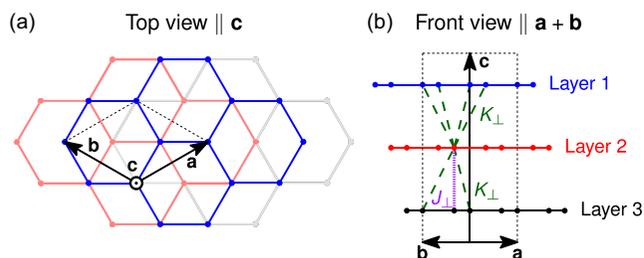

FIG. 7. $R\bar{3}$ crystal structure and interlayer couplings. The three inequivalent honeycomb layers are shown in black, red, and blue. The dashed rhombus indicates the crystallographic unit cell, consisting of two spins per layer. (a) Top view, with a viewpoint along the crystallographic \mathbf{c} direction. (b) Front view, with a viewpoint along an in-plane direction perpendicular to a Ru-Ru bond. The interlayer couplings J_{\perp} and K_{\perp} are depicted in dashed green and dotted purple lines, respectively.

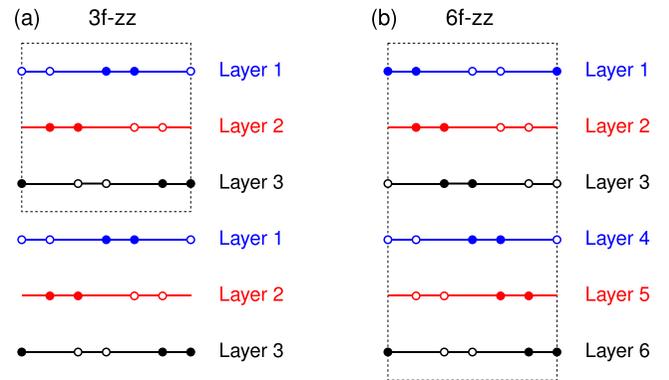

FIG. 8. Two different stackings of in-plane zigzag configurations. The view is along the $\mathbf{a}+\mathbf{b}$ direction as in Fig. 7(b) (perpendicular to a Ru-Ru bond). Spins that point in the same direction are represented by the same (filled or open) symbol; the different colors denote crystallographically inequivalent layers. The magnetic unit cells are indicated by dashed rectangles. (a) Threefold zigzag stacking (3f-zz). (b) Sixfold zigzag stacking (6f-zz). Note that in (a) spins directly above each other point in different directions (antiferromagnetic alignment), while they point in the same direction (ferromagnetic alignment) in (b).

phase calculation at 3.5 T, which is explained by the overall decrease of the order parameter. The resulting structure factor in Fig. 5(c) agrees well with the observed intensities. From the experimental data, it is not clear whether intensity is present at $L = \pm 2.5$, since the expected signal is within the level of the experimental noise. The Γ -point intensities from Fig. 5(b) are modeled in Fig. 5(d). Two additional effects of the external field on the ordered structure are included. First, there is a 10% uniform moment in the honeycomb planes along the field direction, which produces the magnetic peaks at $L = \pm 3$. These were unobservable in the experiment, since they lie on top of intense nuclear peaks. This net ferromagnetic moment is independent of the 3D magnetic structure. Second, there is a 10% AFM moment perpendicular to the field direction that is uniform in each plane, but staggered between neighboring planes. This AFM moment has different effects on the magnetic structure factor in the 3f-zz and 6f-zz configurations. In the three-layer structure, this AFM moment cancels out completely and does not contribute to the structure factor. In the six-layer structure, it causes additional magnetic peaks at half the L value of the nuclear peaks. In $R\bar{3}$, these magnetic peaks appear at $(0, 0, \pm 1.5)$ consistent with the observation from the experiment. In sum, we were able to account for all observed magnetic Bragg peaks with a simple magnetic structure factor model based on two different stackings of the in-plane zigzag configurations.

VI. MICROSCOPIC SPIN MODEL

In this section, we aim to construct a microscopic spin model that describes the experimental findings. As the experiments indicate a field-driven change in the 3D magnetic

structure, this requires a model involving interlayer couplings. Here, we construct such a model and show that it displays a first-order transition from 3f-zz to 6f-zz order for appropriately chosen parameters.

A. 3D spin model

Restricting our attention to low temperatures, we assume a rhombohedral crystal structure with an $R\bar{3}$ space group, implying an undistorted C_3^* symmetry [47,49]. The unit cell contains three honeycomb layers with two spins each; see Fig. 7.

Each spin has one interlayer neighbor that is located either right above or below it, depending on the sublattice index. The strictly vertical spin-spin exchange interaction is compatible with the C_3^* symmetry only for a Heisenberg coupling, denoted as J_\perp in Fig. 7(b). On the level of the next-nearest interlayer neighbors, bond-dependent interactions, such as a Kitaev coupling K_\perp or an off-diagonal Γ_\perp , become symmetry-allowed. We note that the nine next-nearest interlayer neighbors of each spin fall into two classes (with six and three members, respectively) that are distinguished by the presence or absence of a nearest-neighbor intralayer bond in one of the participating layers [40]. In what follows, we will not distinguish between these different next-nearest interlayer neighbors for simplicity.

As noted above, assuming a zigzag magnetic pattern within the honeycomb layers allows two different stackings in the out-of-plane direction; see Fig. 8. $J_\perp > 0$ ($J_\perp < 0$) favors threefold (sixfold) stacking, respectively, independent of the particular spin directions. Interlayer interactions of a purely Heisenberg form will not lead to a field-dependent transition between these two stackings. The existence of such a transition in α -RuCl₃ makes it mandatory to take anisotropic interlayer couplings into account. As mentioned above, these are symmetry-allowed for the next-nearest-neighbor interlayer bonds.

Here, we consider a simple model with the two interlayer couplings only: a Heisenberg nearest-neighbor interlayer coupling J_\perp and a Kitaev next-nearest interlayer neighbor coupling K_\perp . The Hamiltonian may then be written as

$$\begin{aligned} \mathcal{H} = \sum_n \left\{ \sum_{(ij)_\gamma} [J_1 \mathbf{S}_{n,i} \cdot \mathbf{S}_{n,j} + K_1 S_{n,i}^\gamma S_{n,j}^\gamma] \right. \\ \left. + \Gamma_1 (S_{n,i}^\alpha S_{n,j}^\beta + S_{n,i}^\beta S_{n,j}^\alpha) \right\} + \sum_{\langle\langle ij \rangle\rangle} J_3 \mathbf{S}_{n,i} \cdot \mathbf{S}_{n,j} \\ + J_\perp \sum_{(ni,mi)} \mathbf{S}_{n,i} \cdot \mathbf{S}_{m,i} + K_\perp \sum_{\langle\langle ni,mj \rangle\rangle_\gamma} S_{n,i}^\gamma S_{m,j}^\gamma \\ - \mu_B \mathbf{B} \cdot \mathbf{g} \sum_{ni} \mathbf{S}_{n,i}, \end{aligned} \quad (1)$$

where the indices n, m label the layers, and i, j label the sites within a given layer. In the above equation, the first two lines correspond to the usual intralayer interaction [35–37], while the third line denotes the interlayer interactions. The fourth

line is the Zeeman term for a uniform magnetic field \mathbf{B} , with μ_B the Bohr magneton. We assume a diagonal g tensor, $g = \text{diag}(g_a, g_b, g_c)$ in the crystallographic $(\mathbf{a}, \mathbf{b}, \mathbf{c})$ basis, with isotropic in-plane elements $g_a = g_b \equiv g_{ab}$, consistent with C_3^* symmetry. For the intralayer interactions, we use [18,36,37]

$$(J_1, K_1, \Gamma_1, J_3) = (-0.1, -1, 0.5, 0.1)A, \quad (2)$$

where $A > 0$ sets the overall energy scale. Within a purely 2D modeling, this set of intralayer couplings fits well various experiments [9,10,13,21,22,28], but might require modifications upon the inclusion of sizable interlayer couplings [40]. To constrain the parameter space, we hence assume for simplicity that both interlayer couplings are much smaller than the intralayer couplings, $|J_\perp|, |K_\perp| \ll A$. Apart from the individual signs of J_\perp and K_\perp , which will be constrained below, this leaves us with a single free parameter in our model, corresponding to the ratio J_\perp/K_\perp . This turns out to be sufficient to describe well the qualitative features of the experiment. The model, therefore, realizes a minimal theoretical description of the field-induced transition observed in the thermodynamic and neutron-diffraction experiments. We emphasize, however, that such phenomenological modeling does not allow us to fully determine the size and precise nature of the interlayer interactions in α -RuCl₃.

B. Phase diagram

In the limit of $|J_\perp|, |K_\perp| \ll A$, the classical ground state of \mathcal{H} can be found by minimizing the energy within each layer first and then considering the coupling between the layers as a perturbation. The ground state of the system with $J_\perp = K_\perp = 0$ is a zigzag pattern in each layer with the different stackings being degenerate. Small, but finite, J_\perp and K_\perp lift the degeneracy and stabilize either 3f-zz or 6f-zz, depending on the signs and relative sizes of the interlayer couplings. Previous modeling of the magnon spectrum at high fields [40] suggested antiferromagnetic $J_\perp > 0$. Antiferromagnetic J_\perp favors the 3f-zz configuration. This configuration is in agreement with the measurements at low field in the zz1 phase of α -RuCl₃, as discussed above. At intermediate fields between B_{c1} and B_{c2} in the zz2 phase of α -RuCl₃, the structure factor modeling indicated a coexistence of 3f-zz and 6f-zz. The change of the zigzag stackings as a function of field suggests an exchange frustration mechanism arising from the interlayer couplings. With antiferromagnetic $J_\perp > 0$, such an interlayer frustration can be achieved by assuming ferromagnetic $K_\perp < 0$. In fact, using this sign structure of the two interlayer couplings and appropriate chosen magnitudes, we indeed find a transition between a 3f-zz configuration at low fields and a 6f-zz configuration at intermediate fields, before the zigzag order is completely destabilized at the transition to the disordered phase, in agreement with the experiment. Within our simple interlayer model and for the present set of intralayer couplings [Eq. (2)], this occurs for $\mathbf{B} \parallel \{1, 1, 0\}$ within a narrow parameter range $1.1165 < (-K_\perp)/J_\perp < 1.1489$. The emergence of this field-induced transition between the different zigzag stackings can be under-

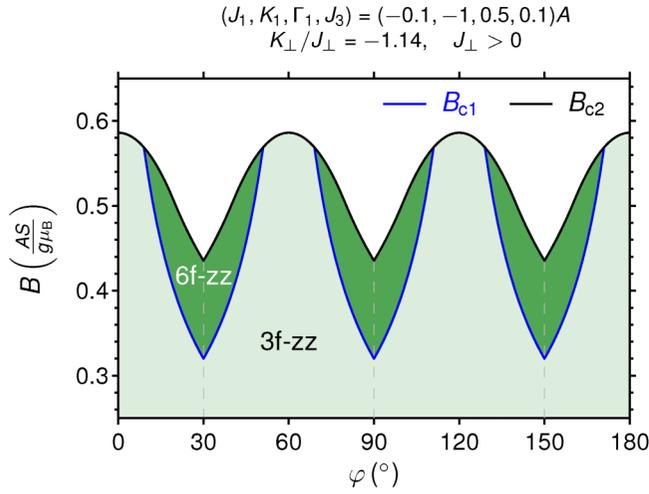

FIG. 9. Classical phase diagram of a microscopic spin model as a function of magnetic field B and in-plane angle φ in the limit of small interlayer couplings, $|K_{\perp}|, |J_{\perp}| \ll A$, with $(-K_{\perp})/J_{\perp} = 1.14$. 3f-zz and 6f-zz denote ordered zigzag configurations with threefold and sixfold layer periodicity, respectively. The experimental phases zz1 and zz2 in Fig. 1 are described by 3f-zz and a coexistence of 3f-zz and 6f-zz, respectively. B_{c1} (blue) denotes the first-order transition between different zigzag stackings; B_{c2} (black) denotes the transition to the disordered phase.

stood as a consequence of the inhomogeneous canting of the spins for $\mathbf{B} \parallel \{1, 1, 0\}$, which leads to a different dependence on the canting angles of the energies of the 3f-zz and 6f-zz states.

By contrast, for $\mathbf{B} \parallel \{1, 0, 0\}$, the canting is homogeneous, and the difference between the 3f-zz and 6f-zz energies can be written as

$$\frac{\Delta E}{NS^2} = [-J_{\perp} + K_{\perp}(\cos^2 \theta - \sqrt{2} \sin 2\theta)] \frac{1 - \cos 2\vartheta_B}{2}, \quad (3)$$

where $\theta \equiv \theta(\Gamma_1/K_1) \in [-\arctan(1/\sqrt{2}), 0]$ parametrizes the direction of the spins at zero field [37], and $\vartheta_B \equiv \vartheta(B) = \angle(\mathbf{S}_i, \mathbf{B}) \in (0, \pi/2]$ is the homogeneous canting angle. N is the total number of spins, and $S = |\mathbf{S}| = 1/2$ for α -RuCl₃. For fixed couplings, the energy difference is therefore always either positive or negative, but it cannot change sign as a function of the field strength B . For $\mathbf{B} \parallel \{1, 0, 0\}$, a field-induced transition between 3f-zz and 6f-zz is therefore not possible within our classical model and for infinitesimal interlayer couplings. We have checked that this remains true when small off-diagonal interlayer couplings Γ_{\perp} are taken into account.

The full classical phase diagram of our microscopic model as a function of the in-plane angle φ is shown in Fig. 9. Here, we have chosen $(-K_{\perp})/J_{\perp} = 1.14$ with $J_{\perp} > 0$. We recall that we work in the limit $|J_{\perp}|, |K_{\perp}| \ll A$, where the phase diagram only depends on the ratio of J_{\perp} and K_{\perp} and not on their individual magnitudes. The phase diagram illustrates that the threefold zigzag stacking (3f-zz) is stabilized for small fields, while a transition to an intermediate ordered phase with

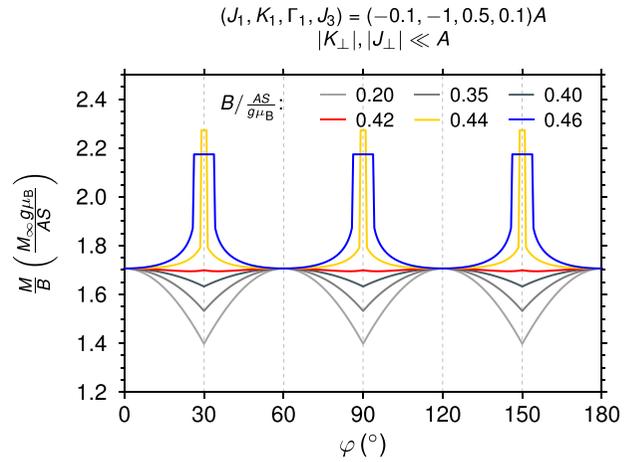

FIG. 10. Classical magnetization (M/B) at various fields in the microscopic spin model as a function of in-plane angle φ in the limit of small interlayer couplings, $|K_{\perp}|, |J_{\perp}| \ll A$, where A sets the overall energy scale.

sixfold zigzag stacking (6f-zz) is found at elevated in-plane fields perpendicular to Ru-Ru bonds. The minimal microscopic theory presented here gives a satisfactory explanation for the observed features in the zz1 and zz2 phases with one exception: It does not predict the small inter-layer staggered antiferromagnetic component necessary to produce the peaks seen in the zz2 phase at $(0, 0, \pm 1.5)$. Importantly, the transition at B_{c1} is first-order, such that coexistence of the 3f-zz and 6f-zz configurations, and therefore their Bragg peaks, can be naturally expected in its vicinity as a consequence of hysteresis effects. We note that a first-order transition from zz1 to zz2 at B_{c1} is consistent with other thermodynamic measurements reported in the literature [22,50,51].

C. Magnetization curves

The magnetization at fixed field strengths as a function of the in-plane angle φ is shown in Fig. 10. The low-field limit of this magnetization curve has previously been discussed in Ref. [37]. In this limit, the magnetization is maximal for fields along Ru-Ru bonds and minimal for fields perpendicular to Ru-Ru bonds, with a characteristic kink that can be understood as a domain switching effect. Increasing the field strength now shifts these minima upwards, such that the magnetization becomes nearly φ -independent for fields just below $B_{c2}(30^\circ)$, until eventually the maxima and minima exchange for fields between $B_{c2}(30^\circ)$ and $B_{c2}(0^\circ)$, in qualitative agreement with the experiment. In the polarized phase, the magnetization curve is flat, which is a classical property that will change upon the inclusion of quantum fluctuations [37].

VII. DISCUSSION

The comparison of the experimental and theoretical results in terms of the angle-dependent phase diagrams [Figs. 1(b) and 9], as well as the magnetization curves [Figs. 3(g) and 10], reveals that the key features of the experiment are reproduced

by the model calculation: (i) A first-order phase transition occurs at a critical field B_{c1} between zigzag structures with threefold and sixfold stacking. (ii) Both the critical fields and the magnetization curves have (approximately) a 60° periodicity, consistent with the C_3 rotational symmetry of the honeycomb lattice. (iii) The critical fields are maximal for fields along Ru-Ru bonds ($\varphi \equiv 0^\circ \bmod 60^\circ$) and minimal for fields perpendicular to a bond ($\varphi \equiv 30^\circ \bmod 60^\circ$). (iv) The width of the intermediate phase is maximal when the critical field is minimal, and vice versa. (v) For fixed low fields, the magnetization M is maximal for $\varphi \equiv 0^\circ \bmod 60^\circ$ and has kinklike minima at $\varphi \equiv 30^\circ \bmod 60^\circ$. (vi) At fixed elevated fields close to the transition to the disordered phase, on the other hand, the maxima and minima in the magnetization are exchanged as a function of φ .

VIII. CONCLUSIONS

We have demonstrated the existence of a field-induced intermediate ordered phase in α -RuCl₃ at fields just below the field where the magnetic order is found to be suppressed completely. This phase is characterized by an in-plane zigzag configuration with a stacking periodicity in the out-of-plane direction that is doubled in comparison with the low-field zigzag phase. The fact that the transition at B_{c1} involves a change of the 3D magnetic structure shows that interlayer interactions are important in α -RuCl₃ and should be included in the minimal model Hamiltonian [40]. We have proposed a simple model including Heisenberg as well as Kitaev interlayer interactions that describes the two different zigzag stackings, their field-induced transition, as well as the magnetization measurements qualitatively well. We emphasize, however, that this analysis does not enable us to draw conclusions concerning the absolute value of the interlayer interactions in α -RuCl₃. The previous 3D modeling [40] of the out-of-plane neutron-scattering data [11] suggested a nearest-neighbor interlayer coupling of the order of $J_\perp \lesssim 1$ meV. The present results indicate that bond-dependent interlayer interactions of the same order may play an equally important role. While such interactions are allowed by symmetry and therefore likely to be present, a microscopic mechanism that explains their significance is currently not known. In light of our results, we believe that some of the previous analyses and interpretations of experimental data in α -RuCl₃, based on strictly 2D modeling, need to be revisited taking the effects of finite interlayer interactions into account.

Finally, we note that the data presented here are not of sufficient resolution at high fields to comment on potential additional phase transitions in the disordered regime [11,20,25,27]. The ac susceptibility data appear mostly featureless above 8 T; however, an additional small kink can be seen between 8 and 10 T in Fig. 3(e), also visible in the false color plot in Fig. 1(a). This might be related to the topological transition out of a potential QSL phase [11,25].

APPENDIX: DETAILED CUTS THROUGH THE NEUTRON-DIFFRACTION DATA

Figure 11 shows cuts through the \mathbf{M} points taken within the honeycomb plane. Each of the four \mathbf{M} points $(0.5, 0, L)$, $(0, 0.5, L)$, $(0, -0.5, L)$, and $(-0.5, 0, L)$ is cut in two different directions indicated in the inset of Fig. 11(a). While panels (a), (b), (e), and (f) are cuts along $(-H, H)$, panels (c), (d), (g), and (h) are cuts along (K, K) .

Panels (a)–(d), which are taken at integer L , show that the magnetic Bragg peaks remain at commensurate positions upon entering the zz2 phase (red data points). The only difference between 3.5 and 6.6 T is a reduction in intensity. This agrees with the expectation for an overall order parameter upon approaching the point at which magnetic order is destroyed; cf. Fig. 6. The difference in intensities between the four \mathbf{M} points, which also changes under increasing magnetic field, is attributed to the presence of different crystallographic and magnetic domains and their nontrivial field evolutions.

Panels (e)–(h) show the appearance of new magnetic peaks in the zz2 phase (red data points) at half-integer L values, which are approximately one order of magnitude weaker compared to the ones at integer L . These also appear at commensurate positions and again show differences in intensities between the four \mathbf{M} points. Since they are absent in the zz1 phase (blue data points), their appearance clearly marks the entrance into a new thermodynamic phase.

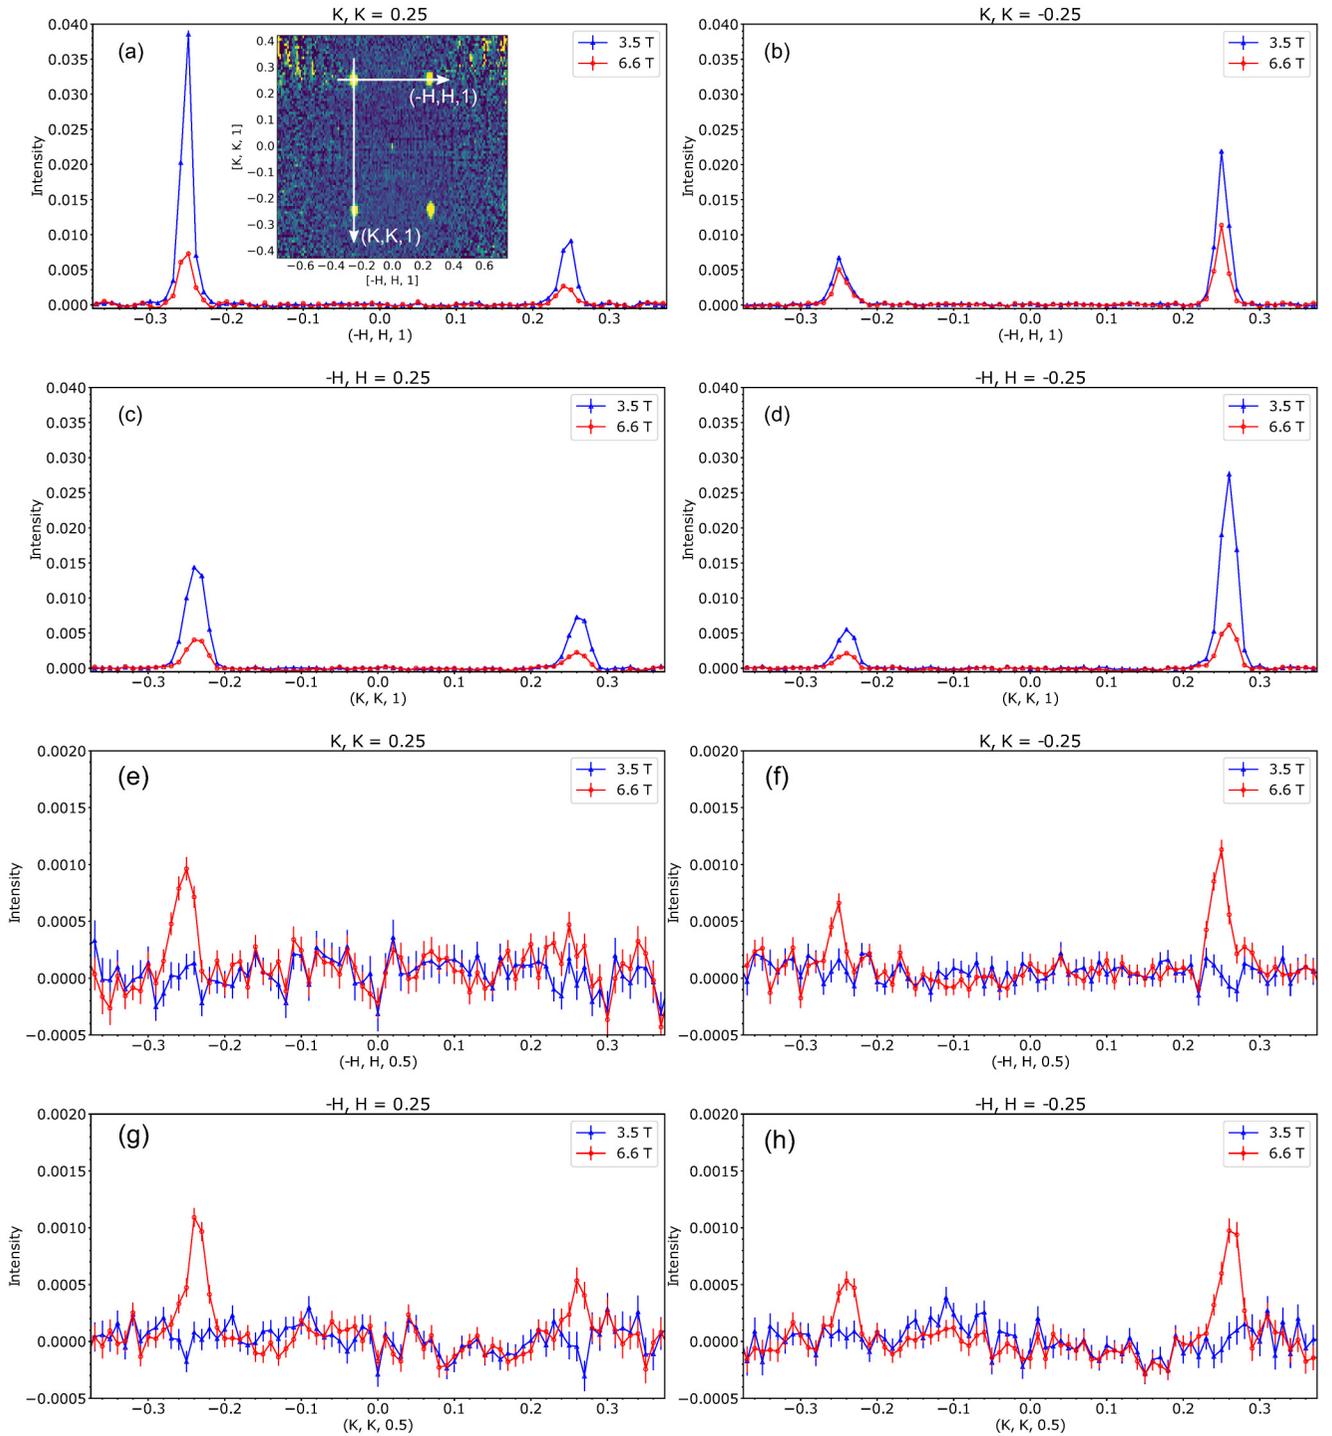

FIG. 11. 1D cuts through the neutron-diffraction data in the honeycomb plane at 3.5 and 6.6 T. Panels (a)–(d) show cuts with $|L| = 1$, and (e) and (f) show cuts with $|L| = 0.5$. The data are integrated over the perpendicular directions by ± 0.03 r.l.u. in the honeycomb plane, and by ± 0.025 r.l.u. along L . In addition, the data are averaged over positive and negative L . The inset of panel (a) shows the direction of the cuts in the honeycomb plane. Note the difference in y-axes scaling between panels (a)–(d) and (e)–(h).
